Abstract

In this paper, we present a model of the atom that is based on a nonclassical logic called paraconsistent logic (PL), which has the main property of accepting the contradiction in logical interpretations without the conclusions being annulled. The proposed model is constructed with an extension of PL called paraconsistent annotated logic with annotation of two values (PAL2v), which is associated with an interlaced bilattice of four vertices. We use the logarithmic function of the Shannon entropy *H*(*s*) to construct the paraconsistent equations and thus adopt a probabilistic model for representations in quantum physics. Through analyses of the interlaced bilattice, comparative values are obtained for some of the phenomena and effects of quantum mechanics, such as superposition of states, wave functions, and equations that determine the energy levels of the atomic shells of an atom. At the end of this article, we use the hydrogen atom as a basis for the representation of the PAL2v model, where the values of the energy levels in six orbital shells are obtained. As an example, we present a possible method of applying the PAL2v model to the use of Raman spectroscopy signals in the detection of lubricating mineral oil quality.

Keywords: Paraconsistent logic, quantum computation, hydrogen atom, Raman spectroscopy, applied physics.

Introduction

The model of the atom was presented by Niels Bohr in 1913, where he proposed that electrons are particles with two kinds of motions in atoms. In the Bohr model, the electrons either move continuously around the nucleus in certain stationary orbits or discontinuously jump between these orbits [23][29]. Subsequently, with the advances in quantum theory, new concepts, such as the ideas of superposition of states and quantum entanglement, have been proposed. Currently, the physical state of an electron is described by a wave function and in the foundations of quantum mechanics; the wave function is a description of the random discontinuous motion of particles. Moreover, the data on the physical properties of particles are uncertain, and all of the analyses are probabilistic [4][18][35]. The square of the modulus of the wave function represents not only the probability of a particle being found at a certain location but also the probability of the particle being there [22][35][28][30][31].

In 1926, Schrödinger proposed a partial differential equation for the wave functions of particles, such as electrons. The state of a system at a given time is described by a complex wave function, which is also referred to as the state vector in a complex vector space, and this abstract mathematical object enables the calculation of the probabilities of the outcomes of concrete experiments [7][36][37]. In 1927, Heisenberg proposed the uncertainty principle, which shows the formal inequality relating the uncertainty of position Δ_x and the uncertainty of momentum Δ_p, as follows [9]:

$$\Delta_x \Delta_p \geq \frac{h}{2} .$$
(1)

The electrons may be considered (to a certain probability) to be located somewhere within a given region of space. However, their exact positions are unknown [4][7][18][27][35]. The probability density is obtained using the square of the amplitude of the wave function, which usually involves a complex quantity [9]. Thus, its value is derived by multiplication with the conjugate complex, as follows [4][7][25][26[27]:

$$\left| \psi \right|^2 = \psi_{(x,t)}^{*} \psi_{(x,t)} .$$
(2)

If the wave function is a representative of the sum of probabilities that describe a particle, then it needs to be normalized, as follows [18][19][22][23][28]: $\int_{-\infty}^{+\infty} \psi^{*}_{(x,t)} \psi_{(x,t)} dx = 1$.

With respect to the logic applied to quantum mechanics among various studies of quantum probabilistic logic formalism, one of the most important search was developed by von Neumann in 1932 [36][37][38]. In his work, von Neumann assumed that each physical system is associated with a Hilbert space *H* (separable), with its unitary vectors corresponding to possible physical states of the system [23]. Each real "observable" random quantity is represented by a self-regulated operator *A* in *H*, whose spectrum is the set of possible values of *A*.

According to the previous works, mathematics in quantum mechanics can be considered a nonclassical probability calculation, which is supported by a nonclassical propositional logic [4][9][27][22][24].

Nonclassical logics are created with the purpose of opposing the binary principles of classical logic, thus providing better conditions for the construction of physical–mathematical models with more approximate results. Currently, there are several types of nonclassical logics, only those logics that are indestructible in the presence of the contradiction are paraconsistent. Therefore, paraconsistent logic (PL) is a non-classical logic that has, as its fundamental characteristic, the opposition to the principle of non-contradiction [1][2][10][11]. The fundamental theory of PL has been developed in the area of philosophical logic [14], and a formal framework for inconsistent theories was proposed by da Costa [21][14]. Further details of the logical formalization of PL, the mathematical implications, and their theorems can be found in [3], [10], and [11] [21].

Blair and Subrahmanian [6] presented applications of PL to logical programming and extended the formalization of three-valued semantics. With this initial work, a theory was developed for possibly inconsistent logic programs using a lattice also known as Belnap's four-valued logic [8], where the set of truth values of four-valued logic is defined as $\tau = \{ t, f, \top, \bot \}$, in which *t, f, ⊤,* and *⊥* are propositions in the language of a program, and they denote true, false, contradictory, and paracomplete, respectively. The set of truth values τ comprises a complete lattice under the ordering ≤, such that $\bot \le x \ge \top$ for $x \in \tau = \{t, f\}$ [10][11][38].

An extended form of PL, the paraconsistent annotated logic (PAL), which has an associated lattice, has been investigated and applied to several fields of science [2][9][20][29][35]. In data analysis systems, the PAL can derive an annotation composed of two degrees of evidence from different sources of information and, in this case, is named paraconsistent annotated logic with annotation of two values– PAL2v [12][13]. The first concepts of PAL2v, which can be applied to artificial intelligence, are presented in [12].

As presented in [2], [12], [13], and [14], in the application of PAL2v, the associated lattice is considered an abstract universe τ, where a negation operator allows logical interpretations to result in paraconsistent equations. In the annotation, the first degree of evidence is favorable for the proposition *P* and is represented by the symbol μ, and the second degree of evidence is unfavorable for the proposition *P* and is represented by the symbol λ. These degrees of evidence are normalized, classified as a set of real numbers, and contained in the closed interval [0,1]. The annotation assigns a logical state to the proposition *P*. Thus, the information in PAL2v is a paraconsistent logical signal represented by the proposition *P* with the subscript of the annotation as $(\mu, \lambda): P_{(\mu,\lambda)}$, where the annotation is composed of a pair of the degrees of favorable evidence (μ) and unfavorable evidence (λ).

Figure 1(a) shows the lattice FOUR associated with PAL and the representations of the extreme logical states in their vertices through the annotation (μ, λ) of PAL2v [13][14][15].

As discussed in [12][13], and [17], this representation of PAL2v has been recently investigated using an interlaced bilattice also known as the bilattice of Belnap [5][7][14]. A bilattice is a structure $B = < B, \le_t, \le_k >$, where B is a nonempty set, and $< B, \le_k >$ and $< B, \le_t >$ are both bounded lattices, that is, with bottom and top elements. In studies of bilattice, the symbols, $\otimes k$ and $\oplus k$ are used to denote the meet and join operations that correspond to $\le_k$, respectively, and $\otimes t$ and $\oplus t$ are used to denote the meet and join operations that correspond to $\le_t$, respectively [5][15]. The partial order $\le_k$ is intended to represent the knowledge or information order, and $\le_t$ is intended to represent the truth order [8].

Figure 1(b) shows the interlaced bilattice of Belnap with the ordering $\leq_t$ and $\leq_k$ and the representations of the extreme logical states in their four vertices, *t*, *f*, ⊤, and ⊥, which denote truth, falsity, both, and none, respectively [5][13].

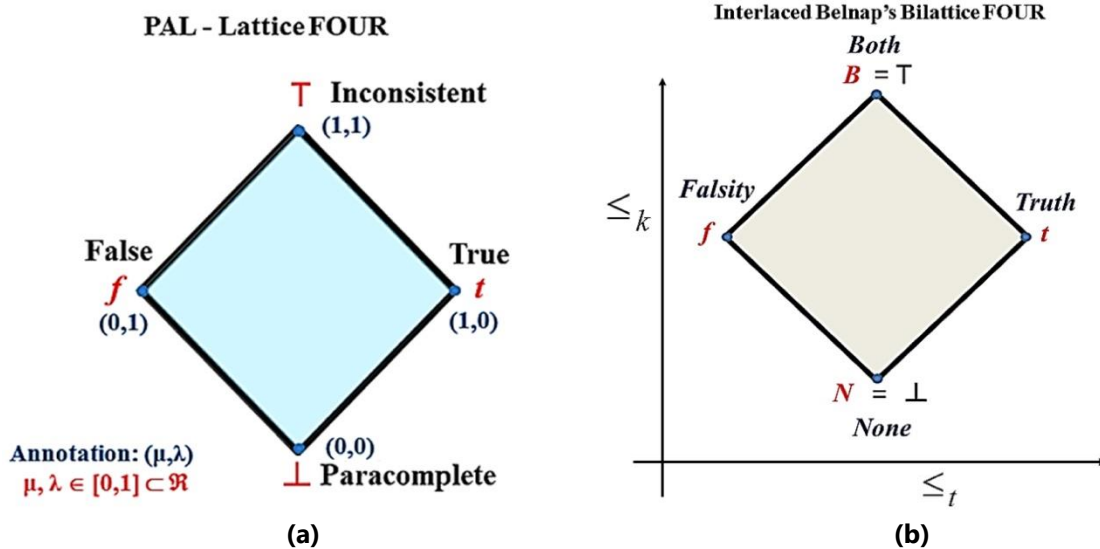

Figure 1. Lattices associated with nonclassical logics –PAL and four-valued logic. (a) lattice FOUR associated with PAL2v and representations of the extreme logical states in their vertices through the annotation (μ, λ); **(b)** interlaced bilattice of Belnap with the ordering $\leq_t$ $\leq_k$ and four extreme logical states represented in their vertices.

The paraconsistent equations are obtained from mathematical transformations that map the values arranged in a unitary square on the Cartesian plane (USCP) to the associated bilattice of PAL2v [5][12]. Initially, the degrees of evidence of PAL2v are considered on the USCP (which is also known as lattice *κ*), from where their values are mapped to lattice FOUR [13]. Given that, in the USCP, the values are allocated to the *x*- and *y*-axes, the USCP (lattice *κ*) is mapped to the associated lattice *τ* of PAL2v by equating values with the degrees of evidence and implementing the following actions:

(a) expansion of $\sqrt{2}$ from the *x*- and *y*-axes $T_1(X_1,Y_1)=\left(x\sqrt{2}, y\sqrt{2}\right)$; (b) 45° counterclockwise rotation at the origin $T_2(X_2,Y_2)=\left(X_1\cdot\cos\theta - Y_1\cdot\sin\theta, X_1\cdot\sin\theta + Y_1\cos\theta\right)$, where $\cos\theta = \dfrac{1}{\sqrt{2}}$ and $\sin\theta = \dfrac{1}{\sqrt{2}}$; (c) translation of the -1 value from the *y*-axis $T_3(X_3,Y_3)=(X_2, Y_2 -1)$ resulting in $T_3(X_3,Y_3)=(x-y, x+y-1)$.

If x is the value allocated to the *x*-axis of the USCP and y is the value allocated to the *y*-axis of the USCP, then $x=\mu$ and $y=\lambda$. The previously described actions create T_1, T_2, and T_3 transformations, as described in [13] and [14], which results in the following:

$$T_3(X_3,Y_3)=(\mu-\lambda, \mu+\lambda-1). \tag{3}$$

We denote the certainty degree (*Dc*) as X_3 and the contradiction degree (*Dct*) as Y_3 [13][14]:

$X_3 = Dc_{(\mu,\lambda)} \rightarrow$ Certainty degree as a function of μ and λ:

$$Dc_{(\mu,\lambda)} = \mu - \lambda, \tag{4}$$

$Y_3 = Dct_{(\mu,\lambda)} \rightarrow$ Contradiction degree as a function of μ and λ:

$$Dct_{(\mu,\lambda)} = \mu + \lambda - 1. \tag{5}$$

Figure 2(a) shows this mapping with the sequences of actions to obtain the equations of the paraconsistent transformations and associated bilattice of PAL2v in the degrees of certainty and contradiction in the *x*- and *y*-axes.

The maximum negative value of the degree of certainty is −1 at the vertex of the extreme logical state "false" (*f*) and the maximum positive value is +1 at the vertex of the extreme logical state "true" (*t*). For these two conditions, the value of the degree of contradiction will always be 0 $\left(Dct_{(\mu,\lambda)} = 0\right)$.

The maximum negative value of the degree of contradiction is −1 at the vertex of the extreme logical state "paracomplete" (⊥), and the maximum positive value is +1 at the vertex of the extreme logical state "inconsistent" (⊤). For these two conditions, the value of the degree of certainty will always be 0 $(Dc_{(\mu,\lambda)} = 0)$ [25,26]. Furthermore, PAL2v, when applied to quantum mechanics, is called paraquantum logic (PqL).

In the interlaced PqL bilattice, the values are represented by a universe of complex numbers, where the degree of contradiction lies in the imaginary axis and the degree of certainty lies in the real axis, with the origin at the point equidistant from the vertices of the bilattice; therefore, in this point, the degrees of certainty and contradiction are both equal to 0 [13][16].

The paraconsistent logical state ε_τ, which defines the paraquantum logical state [31], is considered the point of intersection between the degrees of certainty $(Dc_{(\mu,\lambda)})$ and contradiction $(Dct_{(\mu,\lambda)})$ located in the bilattice FOUR or the PqL bilattice. Therefore, the paraquantum logical state ε_τ can be expressed as follows [13]:

$$\varepsilon_{\tau(\mu,\lambda)} = \left(Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)} \right). \tag{6}$$

Through mapping, the bilattice associated with PqL becomes a lattice of values, where the equations obtained create pairs of the values of $Dc_{(\mu,\lambda)}$ and $(Dct_{(\mu,\lambda)})$, which define infinite internal points of intersection. Each internal point of intersection composed of a pair of values is a single paraquantum logical state $\varepsilon_{\tau(\mu,\lambda)}$.

The equations obtained from the transformations enable the determination of the distance between the paraquantum logical state represented by a pair of inseparable values $\left(Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)} \right)$ and the extreme logical states represented by the vertices of the bilattice. Given that $Dc_{(\mu,\lambda)}$ and $Dct_{(\mu,\lambda)}$ are dependent on the μ and λ values, the distance between the logical state resulting from $\varepsilon_{\tau(\mu,\lambda)}$ and one of the extreme logical states *t*, *f*, ⊤, or ⊥, represented by the vertices of the PqL bilattice, is dependent on the values of μ and λ considered in the physical world. If we know the paraquantum logical state ε_τ in any region inside the PqL bilattice, then the values of the degrees of evidence can be calculated using the following equations [13][17]:

$$\mu_{(p)} = \frac{1}{2} Dc_{(\mu,\lambda)} + \frac{1}{2} Dct_{(\mu,\lambda)} + \frac{1}{2} \tag{7}$$

and

$$\lambda_{(p)} = \frac{-1}{2} Dc_{(\mu,\lambda)} + \frac{1}{2} Dct_{(\mu,\lambda)} + \frac{1}{2}. \tag{8}$$

Figure 2(b) shows the interlaced PqL bilattice with quadrant operators and paraconsistent equations for reversible logic.

Non-commutation exists between the degrees of evidence of the PqL and is explained by the logical negation operation denoted by the symbol ¬ .

The change of position of the degrees of evidence in the annotation negates proposition *P*. Therefore, given proposition *P*, its logical negation ¬ *P* is represented by the exchange of the degrees of evidence in the annotation, as follows [18][20]]:
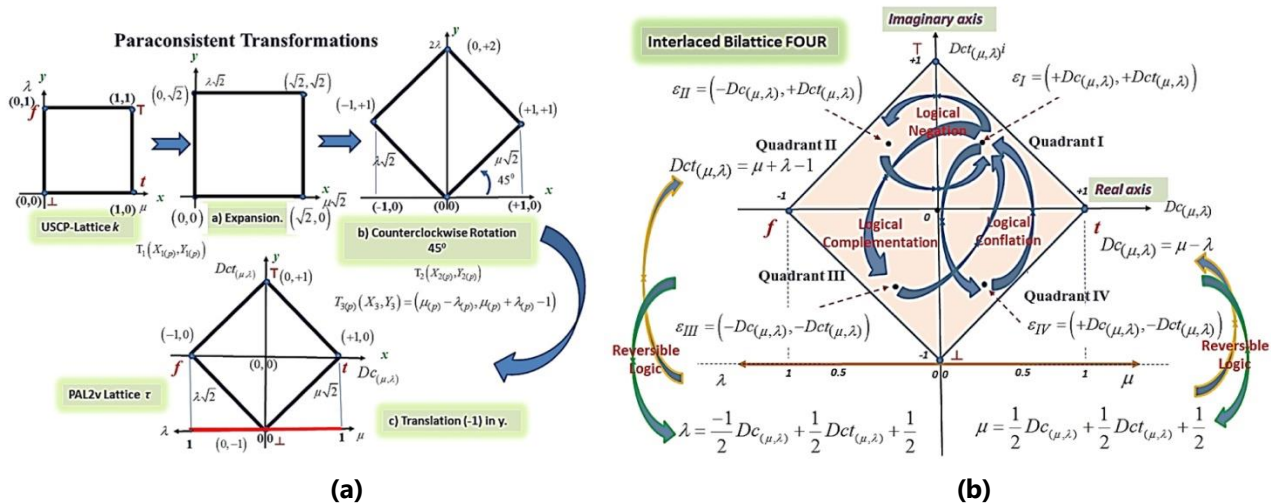

$$\neg(\mu,\lambda) = (\lambda,\mu). \tag{9}$$

Figure 2. Sequences of mapping to obtain the paraconsistent equations and representations in the interlaced PqL bilattice: (a) sequences followed to obtain the equations of the paraconsistent transformations with counterclockwise rotation; **(b)** interlaced PqL bilattice with quadrant operators and paraconsistent equations for reversible logic.

An interlaced bilattice [16][17] in addition to the negation operation expressed in Eq (9) also enables the application of the complementation and conflation operations.

The logical complementation operation in the PqL, denoted by the symbol $\downarrow$, is an explicit complement to the unit of the degrees of evidence in the annotation. Given proposition P and its complement $\downarrow P$, we can express the complementation operation as follows:

$$\downarrow(\mu,\lambda)=(1-\mu,1-\lambda). \tag{10}$$

The logical conflation operation in the PqL, denoted by the symbol   , is explained by the negation operation, followed by the complement to the unit of the degrees of evidence in the annotation [18]. Given proposition P and its conflation P, we can express the conflation operation as follows:

$$(\mu,\lambda)=(1-\lambda,1-\mu). \tag{11}$$

For a logical–mathematical study, the interlaced bilattice associated with PqL can be divided into four quadrants [17]: (a) In Quadrant I, the degrees of certainty and contradiction are positive (there is no operator action on the annotation (μ,λ)); (b) in Quadrant II, the degree of certainty is negative, while the degree of contradiction is positive (this is an action of the logical negation operator $\neg$ over the annotation (μ,λ)); (c) in Quadrant III, the degrees of certainty and contradiction are negative (this is an action of the logical complementation operator $\downarrow$ over the annotation (μ,λ)); and in Quadrant IV, the degree of certainty is positive, while the degree of contradiction is negative (this is an action of the logical conflation operator over the annotation (μ,λ)).

With the negation, complementation, and conflation operations only over the values of the degrees of certainty and contradiction obtained in Quadrant I, the results of the degrees of certainty and contradiction are obtained in the three other quadrants of the interlaced PqL bilattice. Therefore, given that we detect the paraquantum logical state in Quadrant I with the corresponding values of $Dc_{(\mu,\lambda)}$ and $Dct_{(\mu,\lambda)}$, the negation operation results in a negative degree of certainty and an unchanged degree of contradiction. This results in another paraquantum logical state in Quadrant II, which is represented by $\left(-Dc_{(\mu,\lambda)},+Dct_{(\mu,\lambda)}\right)$ [16][17]. Similarly, the complementation operation on the values of the degrees of certainty and contradiction in

Quadrant I results in negative values for both the degrees of certainty and contradiction. This result defines the paraquantum logical state in Quadrant III, which is represented by $\left(-Dc_{(\mu,\lambda)}, -Dct_{(\mu,\lambda)}\right)$.

The conflation operation on the values of the degrees of certainty and contradiction in Quadrant I results in positive values for the degree of certainty and negative values for the degree of contradiction. This result defines the paraquantum logical state in Quadrant IV, which is represented by $\left(+Dc_{(\mu,\lambda)}, -Dct_{(\mu,\lambda)}\right)$ [13].

The paraconsistent model of the atom will be presented and analyzed in this paper. We compare the use of probability in the Shannon entropy function, which will form the degrees of evidence, and the use of Bernoulli distribution to determine the probability value p of the paraconsistent analysis.

Shannon's work emphasizes a fundamental concept, that is, the entropy of the information, which has become well known as the Shannon entropy $H_{(s)}$. The Shannon entropy has complementary interpretations that can be either information quantity (after measurement) or uncertainty (before measurement) in a given probability distribution [33][34]. To establish the current concept that $H_{(s)}$ is a function of entropy, similar to Boltzmann's H theorem, Shannon defined some statistical concepts through the equation

$H_{(s)} = -k \sum\limits_{i=1}^{n} pi \log pi$, where pi is the probability of a system being in cell i of its phase space, and k

corresponds only to a certain unit of measure [33][34][36].

The equation of entropy in the case of two variables, that is, p and q (where $q = 1-p$), is written as follows:

$$H_{(s)} = -k[p \log p + q \log q], \tag{12}$$

where p is the probability, q is its complement ($1-p$), and the constant k depends on the variable used [36][38].

As can be seen in [37] and [31], to obtain the maximum unit value of $H_{(s)}$ in Eq. (12), k is calculated as

$$k = \frac{\log 10}{\log 2} = \frac{1}{\log 2} = \frac{1}{0.301029995} = 3.321928... \ .$$

In 1890, before Bohr introduced his model of the atom, Johannes Rydberg developed formulas describing the wavelengths or frequencies of light in various series of related spectral lines [34]. Later, Bohr expressing results in terms of wavenumber, not wavelength, combined these formulas. These studies resulted in the following equation [35][37]:

$$\frac{1}{\lambda} = R_\infty Z^2 \left(\frac{1}{n_1^2} - \frac{1}{n_1^2} \right), \tag{13}$$

where

λ is the wavelength of the photon (wavenumber=1/wavelength); Z is the atomic number of the atom; n_1 is the principal quantum number of an energy level, for the atomic electron transition; n_2 is the principal quantum number of an energy level for the atomic electron transition, with $n_2 > n_1$; and R_∞ is the Rydberg's

constant, calculated as $R_\infty = \frac{m_e e^4}{8 \in_0^2 h^3 c} = 1.0973731568539 \, m^{-1}$, where m_e is the mass of the electron, e is

the elementary charge of the electron, $\in_0$ is the permittivity of free space, c is the speed of light, and h is the Planck's constant.

The probability p is an outcome that generates the degrees of evidence for the analysis of proposition P for affirmation (true) or refutation (false). One form of representation whose results can be applied to the interlaced PqL bilattice is the Bernoulli trial process [18]. For this representation, we derive the random distribution of variable X, such that $\Pr(X=1) = p$ and $\Pr(X=0) = q$. The expectation value is calculated using $\rightarrow E(X) = p$, and the variance of X is written as Var(X). In this case, the variance is a measure of how much the value of X varies from the expectation $E(X)$ and is defined as $\text{Var(X)} = p - p^2$. The standard deviation of the probability distribution is denoted by the symbol σ and is defined as the square root of the variance Var(X) [16]:

$$\sigma = \sqrt{\mathrm{Var}(X)}. \tag{14}$$

A graph of Var(*X*) as a function of *p* ∈ [0,1] exhibits a parabola that opens downward [16].

In the first stage of the analysis, we show the trajectory of the logical states in the ground state and its main equations obtained in Quadrant I of the interlaced PqL bilattice. Moreover, the negation, complementation, and conflation operations are applied, and the model of the complete atom in the *xy* plane is formed in the perception of an observer in the vector base *X*. In the second stage of the analysis, the modeling equations of the complete atom are presented, and the trajectories of degenerate and nondegenerate quantum states are highlighted. In the third stage of the analysis, the modeling equations of the energy shells are derived from the mapping of the degrees of evidence that differs in terms of the direction of rotation, which is now done clockwise. In this manner, the paraconsistent model of an atom in the *xy* plane is formed in the perception of an observer in the vector base *Y*. Finally, the results of an example of the application of the paraconsistent model of an atom are correlated with the energy values extracted from the Rydberg formulas and presented based on the hydrogen atom. The results of the hydrogen atom show the curves obtained from the analysis of signals using only Quadrant I of the interlaced PqL bilattice.

A method of using Raman spectroscopy signals for the detection of lubricating mineral oil quality is presented with this final model.

1. Materials and Methods

In the construction of the paraconsistent model of the atom, the concepts and equations of PqL and the logarithmic function of the Shannon entropy $H_{(s)}$ are used. These fundamentals, equations, and concepts are applied to the in-depth analysis of the interlaced bilattice associated with PqL. In the proposed model, to represent the probabilistic functions according to the fundamentals of PqL, it is necessary to establish state vectors with unitary modules and that define the orbital paths and energy shells of the atom.

We consider an internal state vector with a unitary module (Pψint) and that has its origin located at the vertex of the true logical state (*t*) of the interlaced PqL bilattice. In this point, $Dc_{(\mu,\lambda)} = +1$ and $Dct_{(\mu,\lambda)} = 0$. Therefore, if the paraquantum logical state of the origin is expressed as $\varepsilon_{\tau} = \left(Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)}\right) = (+1, 0)$, then the variation of the inclination angle of the vector (Pψint) in Quadrant I will be $0 \leq \alpha_{\psi} \leq \dfrac{\pi}{4}$ in radians. Given that the modulus is unitary, the variation of the inclination angle α_{ψ} of the vector Pψint will occur in the interlaced PqL bilattice, with a curvilinear trajectory defined by the paraquantum logical states located at its end. The internal trajectory in Quadrant I of the interlaced PqL bilattice is defined in Eq. (6). For an external state vector with a unitary module (Pψext) and that has its origin at the point equidistant from the vertices of the interlaced PqL bilattice $\varepsilon_{\tau} = \left(Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)}\right) = (0, 0)$, the equation of the paraquantum logical states that form the external trajectory in Quadrant I can be described as a function of the value of α_{ψ} and can be expressed as follows:

$$\varepsilon_{\psi(\alpha\psi)} I = \left(1 - \cos(\alpha\psi), sen(\alpha\psi)\right). \tag{15}$$

This expression is similar to the following function:

$$\varepsilon_{(\mu,\lambda)} I = \left(1 - Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)}\right), \tag{16}$$

where μ and λ are the degrees of evidence.

The external trajectory of the paraquantum logical states in Quadrant I can be completed for the variation of the inclination angle α_{ψ} of another vector, that is, PψCext.

With the same values of μ and λ, an external complementary vector (PψCextII) with a unitary module is created simultaneously, with its origin at the point $\varepsilon_{\tau} = \left(Dc_{(\mu,\lambda)}, Dct_{(\mu,\lambda)}\right) = (0, 0)$ and its angle of inclination

having a variation of $\frac{\pi}{4} \leq \alpha_\psi \leq \frac{\pi}{2}$ in radians. With the same quantitative values of the degrees of evidence, this complementary operation is applied to the degrees of certainty and contradiction, generating the paraquantum logical state $\varepsilon_{(\mu,\lambda)} = \Psi_{I2}(PqL)E1$.

The generated paraquantum logical state establishes the orbital trajectory of the state vector Pψ_{I2}, whose inclination presents a variation of 45° to 90°, that is, an angular variation of $\frac{\pi}{4}$ to $\frac{\pi}{2}$ radians. The paraquantum logical state, which features the orbital trajectory at the end of the new complementary state vector, with the completed action in the degrees of certainty and contradiction, is represented by $\varepsilon_{(\mu,\lambda)}II = \uparrow \varepsilon_{(\mu,\lambda)}I$ in the following expression:

$$\varepsilon_{(\mu,\lambda)}II = \left(1 - Dct_{(\mu,\lambda)}, 1 - \left(1 - Dc_{(\mu,\lambda)}\right)\right). \tag{17}$$

In Quadrant I of the interlaced PqL bilattice, μ and λ are represented by probabilistic functions $\mu_{(p)}$ and $\lambda_{(p)}$, which must present results that have their values varying simultaneously in the corresponding intervals, that is, $0.5 \leq \mu_{(p)} \leq 1.0$ and $0.5 \leq \lambda_{(p)} \leq 1.0$, respectively.

Figure 3 shows Quadrant I of the interlaced PqL bilattice with the state vector with a unitary module, which, with the variation of the inclination angle α_ψ, establishes the internal trajectory of the paraquantum logical states. In the same mode, the external state vectors Pψ_{extI} and Pψ_{CextI} establish the complete external trajectory of Quadrant I.

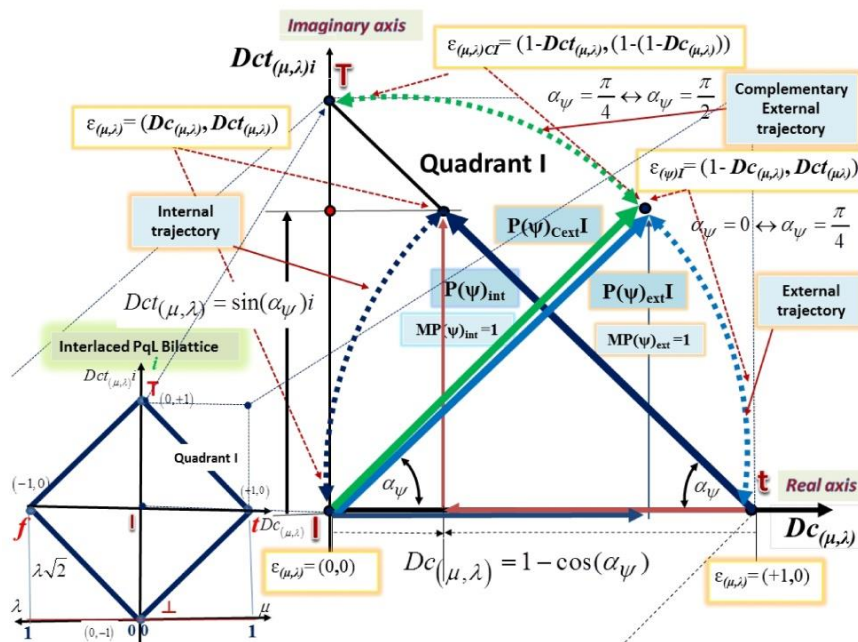

Figure 3. Quadrant I of the interlaced PqL bilattice, with the internal state vector (Pψ_{int}) and two external state vectors (Pψ_{extI} and Pψ_{CextI}) that establish the internal and external orbit trajectories of the paraquantum logical state $\varepsilon_{(\mu,\lambda)}$.

1.1 Representation of the Degrees of Evidence of PqL as Probabilistic Functions

First, we consider that $\mu_{(p)}$ is a probabilistic function $f_{(p)} = X$, such that $p \in \Re$ and it is contained in the closed interval [0,1]. Therefore, *p* represents a probability value, and the normalized values *X* and *X'* should be

adapted to the interlaced PqL bilattice. The two probability values must also be presented to form an annotation.

We also consider that as an initial condition, the two probabilistic sources 1 and 2 are out of phase at the angle Θ, such that in the amplitude variation of the probability value *p*, the probabilistic function of source 2 generates another function; that is, $\lambda_{(p)} = X'$. These two probabilistic functions must have the following characteristics: a) when *X* is at its maximum unitary value, that is, $\mu_{(p)} = X = 1$, the difference between *X* and *X'* will be equal to $\Delta_{(Xp)} = \left(X - X' \right) \rightarrow \Delta_{(Xp)} = \left(1 - \frac{1}{\sqrt{2}} \right)$; (b) when *X* is at half its maximum value, that is, $\mu_{(p)} = X = \frac{1}{2}$, the difference between *X* and *X'* will be null $\Delta_{(Xp)} = X - X' = \left(\frac{1}{2} - \frac{1}{2} \right) = 0$.

From the reference probability value at source 1, which is considered a degree of favorable evidence $\mu_{(p)}$, the degree of unfavorable evidence $\lambda_{(p)}$ under the previously mentioned conditions is derived as follows:

$$\lambda_{(p)} = \sqrt{\frac{\mu_{(p)}}{2}} . \tag{18}$$

From Eq (4), the degree of certainty of the interlaced PqL bilattice, which is now a probabilistic function, can be calculated as follows:

$$Dc_{(p)} = \mu_{(p)} - \sqrt{\frac{\mu_{(p)}}{2}} . \tag{19}$$

In the same manner, the degree of contradiction shown in Eq (5) is also a probabilistic function, which can be calculated as follows:

$$Dct_{(p)} = \mu_{(p)} + \sqrt{\frac{\mu_{(p)}}{2}} - 1 . \tag{20}$$

From Eq (6), the paraquantum logical state ψ_PqL that appears in the interlaced PqL bilattice will be represented by two probabilistic functions, as follows:

$$\psi\tau_{(p)} = \left(Dc_{(p)}, Dct_{(p)} \right) . \tag{21}$$

In the representation of the functions, the paraquantum logical state $\psi\tau_{(p)}$ will form a probabilistic trajectory into the interlaced PqL bilattice. Moreover, the paraquantum logical state ψ_PqL will form a probabilistic trajectory out of the interlaced PqL bilattice, with the origin of the state vector at the point equidistant from the vertices, thereby located where $Dc_{(p)} = 0$ and $Dct_{(p)} = 0$. In this case, the paraquantum logical state ψ_p that forms an external orbit trajectory will be constructed with two probabilistic functions, as follows:

$$\psi_{(p)} = \left(1 - Dc_{(p)}, Dct_{(p)} \right), \tag{22}$$

where $Dc_{(p)}$ is obtained using Eq (19), and $Dct_{(p)}$ is obtained using Eq (20).

1.2 Representation of Fundamental PqL-Equations

In this work, we will construct a paraconsistent model of the atom using the Shannon entropy to operate as a probabilistic function representative of the degrees of evidence (μ, λ) in the interlaced PqL bilattice. In this manner, the fundamental PqL-equations as well as degree of evidence equations will be probabilistic functions, that it will be inserted in the energy equations of the paraconsistent model of the atom. To apply the Shannon entropy function to the PqL equations, we will introduce an adjustment dimensionless value represented by the symbol S_h, which will be called the Shannon normalization factor.

The S_h value is calculated as follows: Being that the Shannon entropy from Eq (12) is represented by the probabilistic logarithmic function $H_{(s)} = -k[p \log p + q \log q]$, the maximum unitary value of $H_{(s)}$ can be obtained when $k = \dfrac{1}{\log 2}$; then we will make a representation of k in which the equality of constants is satisfied as $k = \dfrac{1}{\log 2} = S_h \pi$. Thus, the Shannon normalization factor value S_h is obtained by the equation:

$S_h = \dfrac{1}{\pi \log 2}$, where $\pi = 3.14159265358$, that results at $S_h = 1.057402554$.

With these dimensionless values relationships, the function of Shannon entropy for application in PqL, which we named $H_{(s)PqL}$, can be represented in a normalized mode as follows:

$$H_{(s)PqL} = -S_h \pi [p \log p + q \log q], \tag{23}$$

where π is the constant of value $(\pi = 3.14159265358...)$, p is the probability value, q is the complement of the probability value $[q = (1-p)]$, and S_h is the Shannon normalization factor extracted from k, with $S_h = \dfrac{1}{\pi \log 2} = 1.057402554$.

The variation of the resulting values of the function $H_{(s)PqL}$ is expressed in the range $0 \leq H_{(s)PqL} \leq 1$; therefore, the Shannon's normalized entropy has the variation values contained within the same range as that established for the PqL degrees of evidence.

For the paraconsistent model of the atom, the probabilistic function of the degree of favorable evidence of the PqL $\mu_{(PqL)}$ can be expressed as follows:

$$\mu_{(PqL)} = H_{(s)PqL}, \tag{24}$$

where $H_{(s)PqL}$ is the Shannon entropy function presented in Eq (23).

According to Eq (18), with the inclusion of the Shannon entropy, the probabilistic function of the degree of unfavorable evidence can be expressed as follows:

$$\lambda_{(PqL)} = \sqrt{\dfrac{H_{(s)PqL}}{2}}, \tag{25}$$

where $H_{(s)PqL}$ is the probabilistic Shannon entropy function presented in Eq (23).

With these two last equations, $H_{(s)PqL} = 1$ means high entropy. In this condition, the degree of favorable evidence of the PqL (Eq 24), will be of unitary value $\mu_{(PqL)} = 1$, and the degree of unfavorable evidence (Eq 25), will be $\lambda_{(PqL)} = \dfrac{\sqrt{2}}{2}$. Likewise, $H_{(s)PqL} = 0.5$ means low entropy. In this condition the degree of favorable evidence, by Eq (24), will be $\mu_{(PqL)} = 0.5$, and the degree of unfavorable evidence, by Eq (25), will be $\lambda_{(PqL)} = 0.5$.

The degrees of evidence with their probabilistic representations created by the Shannon entropy function $H_{(s)PqL}$ are used in the equations to obtain the degrees of certainty and contradiction resulting in dimensionless values contained in the range $[-1, +1]$.

Since the PqL equations are functions that deal with normalized dimensionless values between 0 and 1, when multiplied by a known maximum energy value, they will represent the energy value in each condition expressed by the paraquantum logical states. Thus, in the paraconsistent model of an atom, we can consider that these PqL equations involve quantized energies through the values established by the unitary modulus vectors Pψint, Pψext, and PψCextII. In this condition, at the ground-state level of the atom, the degrees of

certainty $Dc_{(PqL)}$ and contradiction $Dct_{(PqL)}$ represent the energy values, which are obtained using the quantized probabilistic evidence degrees.

From Eq (19), the probabilistic certainty degree of the ground state (level E_1) can be calculated as follows:

$$Dc_{(PqL)E1} = H_{(s)PqL} - \sqrt{\frac{H_{(s)PqL}}{2}} . \tag{26}$$

From Eq (20), the probabilistic contradiction degree of the ground state (level E_1) can be calculated as follows:

$$Dct_{(PqL)E1} = H_{(s)PqL} + \sqrt{\frac{H_{(s)PqL}}{2}} - 1 \tag{27}$$

The values of the degrees of certainty and contradiction considered in the set of complex numbers , with their quantized probabilistic functions, represent the energy of the atom. In the proposed paraconsistent model of an atom, the ground state (level E_1) is represented by the point of origin of the real and imaginary axes, which will be located at the point equidistant from the vertices of the interlaced PqL bilattice. In this representation, the paraconsistent logical state ψ_{Pql} that defines the external orbital trajectory in the ground state, representing the complex numbers in Quadrant I, is expressed as follows:

$$\psi_{I1(PqL)E1} = \left(1 - Dc_{(PqL)E1}, Dct_{(PqL)E1}i\right). \tag{28}$$

The probabilistic functions of the paraquantum logical state $\psi_{I(PqL)E1}$ establish the ground state (level E_1) and the external orbital trajectory in the ground state of the model of an atom at the end of the state vector Pψ_{I1} with a unitary module; that is, $M\psi_{E1} = \sqrt{\left(1 - Dc_{(PqL)E1}\right)^2 + \left(Dct_{(PqL)E1}\right)^2}$ or

$$M\psi_{E1} = \sqrt{\left(1 - \left(H_{(s)PqL} - \sqrt{\frac{H_{(s)PqL}}{2}}\right)\right)^2 + \left(H_{(s)PqL} + \sqrt{\frac{H_{(s)PqL}}{2}} - 1\right)^2} , \tag{29}$$

where $H_{(s)PqL}$ is the probabilistic Shannon entropy function presented in Eq (23).

With these logical–mathematical considerations, some concepts of PqL can be compared with the concepts of quantum mechanics on the basis of the equations obtained in Quadrant I of the interlaced PqL bilattice. Therefore, in quantum mechanics, the quantum state is represented by $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$ and the vector norm is represented by $\||\psi\rangle\| = |\alpha|^2 + |\beta|^2$.

The same paraquantum logical state in quantum mechanics will be achieved, with the following relations of equality: $\alpha = \left(1 - Dc_{(PqL)}\right)$ and $\beta = Dct_{(PqL)}$.

The quantum state of the quantum mechanics in the PqL is represented by the following well-known Dirac notation:

$$|\psi\rangle = \left(1 - Dc_{(PqL)}\right)|0\rangle + Dct_{(PqL)}|1\rangle . \tag{30}$$

In general, for *n* number of states related to *En* shells of energies:

$$|\psi_n\rangle = \left(1 - Dc_{(PqL)En}\right)|0\rangle + Dct_{(PqL)En}|1\rangle . \tag{31}$$

The representation of the degrees of certainty and contradiction and the ground state in level E_1 will be unitary ($E_1 = 1$) and is represented by

$$E_{1Total} = \left(1 - \left(H_{(s)PqL} - \sqrt{\frac{H_{(s)PqL}}{2}}\right)\right)^2 + \left(\left(H_{(s)PqL} + \sqrt{\frac{H_{(s)PqL}}{2}}\right) - 1\right)^2 , \tag{32}$$

where the potential energy of the ground state is $E_{P1} = \left(1 - \left(H_{(s)PqL} - \sqrt{\dfrac{H_{(s)PqL}}{2}}\right)\right)^2$, and the kinetic energy of the

ground state is $E_{c1} = \left(\left(H_{(s)PqL} + \sqrt{\dfrac{H_{(s)PqL}}{2}}\right) - 1\right)^2$ and $H_{(s)PqL}$ is the probabilistic Shannon entropy function

presented in Eq (23).

1.3 PqL Energy Equations for the Observer in the Vector Base *X*

In Quadrant I of the interlaced PqL bilattice, the Shannon entropy functions simultaneously create the trajectories of the paraquantum logical states at the ends of two state vectors, thus establishing the ground state (level E_1) of the quantum state of the particle.

The state vector $P\psi_{Cextl}$ constructed with the complementary action, in relation to the original vector $P\psi_{extl}$, has the same characteristics and differs only in terms of the angular variation. For the *X* observer, as defined in the mapping shown in **Fig. 3**, the projections of the real values in the *x*-axis, which represent the potential energy, and the imaginary values in the *y*-axis, which represent the kinetic energy, vary proportionally, indicating the equilibrium of values against the inherent probabilistic uncertainties of quantum mechanics.

The energies of the ground state are represented by the PqL equations, with the adapted function of the Shannon entropy having only the probability *p* as its variable. Using the logical operations of negation, complementation, and conflation, as well as the fundamentals of PqL, we will now define the *n* energy equations that form the *n* atomic shells of the paraconsistent model of the atom. Initially, through these operations, the ground-state energy equations of the three other quadrants of the interlaced PqL bilattice are obtained.

The negation operator applied to the functions of the paraquantum logical states that mark the orbital trajectory of the particle in the ground state of Quadrant I produces Quadrant II, as follows:

$$\neg \psi_{(I)1} = \psi_{(II)1} = (-\alpha, \beta) \rightarrow \psi_{(II)1} = \left(Dc_{(PqL)En} - 1, Dct_{(PqL)En}\right),$$

$$\neg \psi_{(I)2} = \psi_{(II)2} = (\beta - 1, \alpha - 1) \rightarrow \psi_{(II)2} = \left(Dct_{,(PqL)En} - 1, -Dc_{(PqL)En}\right).$$

In Quadrant III, the complementation operator applied to the functions of the paraquantum logical states that mark the orbital trajectory of the particle in the ground state of Quadrant I produces the following expressions:

$$\downarrow \psi_{(I)1} = \psi_{(III)1} = (-\alpha, -\beta) \rightarrow \psi_{(III)1} = \left(Dc_{(PqL)En} - 1, -Dct_{(PqL)En}\right),$$

$$\downarrow \psi_{(I)2} = \psi_{(III)2} = (\beta - 1, 1 - \alpha) \rightarrow \psi_{(II)2} = \left(Dct_{,(PqL)En} - 1, 1 - (1 - Dc_{(PqL)En})\right).$$

In Quadrant IV, the conflation operator applied to the functions of the paraquantum logical states that mark the orbital trajectory of the particle in the ground state of Quadrant I produces the following expressions:

$$\psi_{(I)1} = \psi_{(IV)1} = (\alpha, -\beta) \rightarrow \psi_{(IV)1} = \left(1 - Dc_{(PqL)En}, -Dct_{(PqL)En}\right),$$

$$\psi_{(I)2} = \psi_{(IV)2} = (\beta, 1 - \alpha) \rightarrow \psi_{(IV)2} = \left(1 - Dct_{(PqL)En}, Dc_{(PqL)En}\right).$$

These PqL logical operations create the paraconsistent model of the atom, where the probabilistic trajectory of the particle in the ground state is a unit-radius circle composed of the Shannon entropy functions introduced in the degrees of certainty and contradiction equations.

These probabilistic trajectories related to the ground state are shown in the graphics of the results section.

In this search, we consider that the shells of the atom that relate to the degenerate states are represented by energy that is related to the fundamentally pure state but is not aligned to the *x*-axis of the real values.

In the interlaced PqL bilattice, the degenerate states have different values of contradiction degrees, which bring them close to the extreme logical state of inconsistency in Quadrants I and II and the extreme logical

state of paracompleteness in Quadrants III and IV. In the same manner, the shells of the atom that relate to the nondegenerate states are represented by the energy that is related to the fundamentally pure state. In the interlaced PqL bilattice, the nondegenerate states are aligned to the *x*-axis of the real values and thus to the axis of the degrees of certainty.

The nondegenerate states have the same values of contradiction degrees and different values of certainty degrees, which bring them close to the extreme logical state of true (*t*) in Quadrants I and IV and the extreme logical state of false (*f*) in Quadrants II and III.

With these considerations, for the second atomic shell, the degree of favorable evidence μ is expressed in Eq. (24), and that of unfavorable evidence is expressed in Eq. (25). We can maintain a constant difference between the two degrees of evidence within a reasonable range of the probability variation *p*. For this, the degree of unfavorable evidence can be obtained by multiplication with the degree of favorable evidence, such that $\lambda_{(PqL)EE2} = \mu_{(PqL)E2} \times \lambda_{(PqL)E2}$ or

$$\lambda_{(PqL)EE2} = H_{(s)PqL} \sqrt{\frac{H_{(s)PqL}}{2}} \ . \tag{33}$$

With these values of the degrees of evidence, the degree of certainty for the energy level E_2 will have a constant value over a reasonable range of probability variation *p*. Therefore, $Dc_{(PqL)E2} = \mu_{(PqL)E2} - \lambda_{(PqL)EE2}$ or

$$Dc_{(PqL)E2} = H_{(s)PqL} - \left(H_{(s)PqL} \sqrt{\frac{H_{(s)PqL}}{2}} \right). \tag{34}$$

Moreover, the degree of contradiction for the energy level E_2 can be derived as follows:

$$Dct_{(PqL)E2} = H_{(s)PqL} + \left(H_{(s)PqL} \sqrt{\frac{H_{(s)PqL}}{2}} \right) - 1 , \tag{35}$$

where $H_{(s)PqL}$ is the Shannon entropy function presented in Eq (23).

In the second atomic shell, the degenerate paraquantum logical state will be represented by the function:

$$\psi_{(PqL)E2} = \left(1 - Dc_{(PqL)E2}, Dct_{(PqL)E2} \right) \tag{36}$$

or by the Dirac notation for the *X* observer:

$$|\psi\rangle \psi_{(PqL)E2} = \left(1 - Dc_{(PqL)E2} \right) |0\rangle + Dct_{(PqL)E2} |1\rangle , \tag{37}$$

where $Dc_{(PqL)E2}$ is presented in Eq (34), and $Dct_{(PqL)E2}$ is presented in Eq (35).

Given the relation to the pure state of the ground state, in the second atomic shell, the pure or nondegenerate paraquantum logical state will be represented by the complement expressed in Eq (34) and the function expressed in Eq (27), as follows:

$$\psi_{(PqL)E2\,pure} = \left(1 - Dc_{(PqL)E2}, Dct_{(PqL)E1} \right). \tag{38}$$

These procedures can be continued for *n* atomic shells of the paraconsistent model of the atom.

In **Appendix A** are the equations for the third, fourth, fifth and sixth energy shells used in the paraconsistent model of the atom.

The graphs resulting from the energy shell equations are shown in the results section.

1.4 PqL Energy Equations for the Observer in the Vector Base *Y*

For the interlaced PqL bilattice, the equations that translate this situation can be obtained using the same procedures performed to obtain the equations for calculating the degrees of certainty and contradiction. To derive the equations for the *Y* observer, we initially consider the same probabilistic function used for the *X* observer, with its values allocated to the same USCP (lattice κ). To obtain the degrees of certainty and contradiction for the *Y* observer, we will apply the actions that previously created the transformations that resulted in the degrees of certainty and contradiction, now considering the rotation of 45° to be clockwise.

These actions are as follows: (a) expansion of $\sqrt{2}$ from the x- and y-axes $T_1(X_1,Y_1)=\left(x\sqrt{2},y\sqrt{2}\right)$; (b) 45° clockwise rotation at the origin $T_2(X_2,Y_2)=(X_1\cdot\cos\theta+Y_1\cdot\sin\theta,X_1\cdot\sin\theta-Y_1\cos\theta)$ where $\cos\theta=\dfrac{1}{\sqrt{2}}$ and $\sin\theta=\dfrac{1}{\sqrt{2}}$; (c) translation of the -1 value from the x-axis $T_3(X_3,Y_3)=(X_2-1,Y_2)$, resulting in $T_3(X_3,Y_3)=(x+y-1,x-y)$ or

$$T_{3(p)}(X_3,Y_3)=\left(\mu_{(p)}+\lambda_{(p)}-1,\mu_{(p)}-\lambda_{(p)}\right). \tag{39}$$

For the Y observer, we denote the contradiction degree (*Dct*) as X_3 and the certainty degree (*Dc*) as Y_3: $X_3=Dc\ \rightarrow$ Certainty degree:

$$Dc_{(p)y}=\mu_{(p)}+\lambda_{(p)}-1, \tag{40}$$

$Y_3=Dct\ \rightarrow$ Contradiction degree:

$$Dct_{(p)y}=\mu_{(p)}+\lambda_{(p)}. \tag{41}$$

Therefore, from Eq (39) –transformation $T_{3(p)}$, we obtain the certainty degree equation ($Dc_{(\mu(p),\lambda(p))}$), with its values projected on the y-axis of the lattice τ, and the contradiction degree equation ($Dct_{(\mu(p),\lambda(p))}$), with its values projected on the x-axis of the lattice τ.

In **Fig. 4**(a), the mapping with the sequences of actions of the paraconsistent transformations for the Y observer is shown.

Given that the paraquantum logical state will have its values changed through the modification of the orbital trajectory, for the Y observer, its representation will be at the extremity of the internal state vector of the PqL, originating from the vertex where the inconsistent logical state is located.

For logical negation, the internal state vector will have its origin at the vertex, where the extreme logical state "paracomplete" is located.

Given that the paraquantum logical state $\psi\tau$ is the point of intersection between the degree of certainty (*Dc*) and the degree of contradiction (*Dct*) located in the interlaced PqL bilattice, the representation of the Y observer in the form of a set of complex numbers will be expressed as follows:

$$\psi_{\psi\,\text{int}}Iy=iDc_{(p)}+Dct_{(p)}. \tag{42}$$

An internal state vector with a unitary module and that originates from the inconsistent extreme logical state (T) is derived as follows:

$$M\psi y=\sqrt{\left(Dc_{(p)}\right)^2+\left(Dct_{(p)}\right)^2}. \tag{43}$$

This internal state vector with a unitary module defines the orbital paths within the interlaced PqL bilattice.

The same values represent the external logical state for the ground state (level E_1), which can be expressed as follows:

$$\psi_{\psi\,\text{int}}Iy=i\left(1-Dc_{(p)y}\right)+Dct_{(p)y}. \tag{44}$$

This unitary module of the state vector defines the external orbital trajectory in the PqL bilattice.

The external orbital trajectory is made at the extremity of the external state vector with a unitary module and whose origin is at the point equidistant from the vertices of the interlaced PqL bilattice. Its module is expressed as follows:

$$M\psi Iy=\sqrt{\left(1-Dc_{(p)y}\right)^2+\left(Dct_{(p)y}\right)^2}. \tag{45}$$

The values representing the external logical state of the ground state (level E_1) for the Y observer with the probability values used in the PqL can be derived as follows:

$$\psi_{\psi y}=\left(Dc_{(p)y},Dct_{(p)y}\right). \tag{46}$$

Figure 4(b) shows Quadrant I of the interlaced PqL bilattice with the state vectors and orbit trajectories of the Y observer.
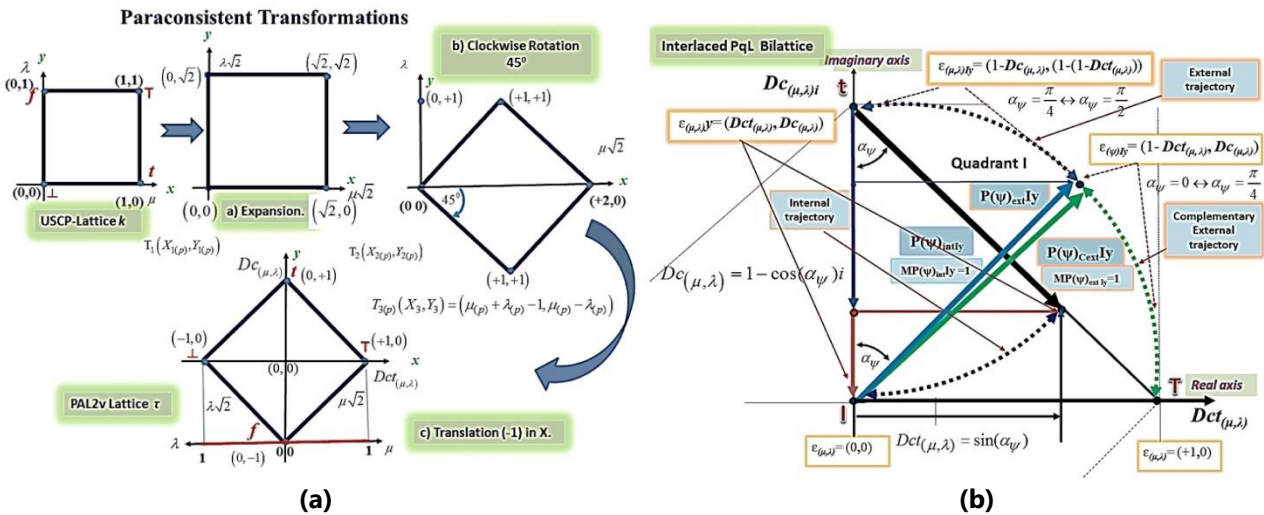

Figure 4. Paraconsistent transformations and state vectors for the *Y* observer: (a) sequences of the paraconsistent transformations for the *Y* observer with clockwise rotation; **(b)** Quadrant I of the interlaced PqL bilattice with the vectors and orbit trajectories of the *Y* observer.

1.5 A Representation of the Paraconsistent Model of the Atom

The mapping sequences of probabilistic evidence degrees with both the *X* and *Y* observers result in equations of superposed paraquantum logical states in Quadrant I of the interlaced PqL bilattice. Using the paraquantum equations, we can present the results of the superposed logical states as two bilattices comprising one superposed plane.

The energy equations for the *Y* observer are represented by the paraquantum logical states with a set of complex numbers, where the imaginary and real values will change depending on the observer. For the *Y* observer, the vector base will be orthogonal to the base *X*. This means that, for the *Y* observer, the imaginary values of the *X* observer will be their real values and the actual values of the *X* observer will be their imaginary values.

In the paraconsistent model, the equations form superposed paraquantum logical states located in the planes of the *X* and *Y* observers. Moreover, variations of the probability values are applied to the equations expressing the orbital trajectories of the particles in the two superposed planes as traces of energy in the overlapping shells of the atom.

In the next section, a paraconsistent model of the atom is constructed with PqL equations formalized with the Shannon entropy function. With the range of probability values (p), we will obtain the degrees of evidence and the degrees of certainty and contradiction forming the paraquantum logical states and energy values to show through the graphical results the individual behavior and its representations that simulate quantum phenomena.

2. Results and Discussion

The graphical results that will be presented are from simulations using the PqL equations. In the simulations with fundamental PqL-equations and for energy shells of the hydrogen atom, the number of sequential steps used was Nmax=100, therefore the probability values (p) are with intervals Δp in the order of 1/100. The value used as the Shannon normalization factor was $S_h = 1.057402554$, and the pi constant used was $\pi = 3.14159265358$.

2.1 Results Related to the Fundamental PqL-Equations of the Paraconsistent Model of the Atom

Figure 6(a) shows the graphs of the results of the degree of favorable evidence $\mu_{(PqL)}$ derived using Eq (24) and the degree of unfavorable evidence $\lambda_{(PqL)}$ derived using Eq (25).

Figure 6(b) shows the variations of the degrees of certainty (Eq 26) and contradiction (Eq 27) and the simulation results of the unitary module M(ψ)I$_1$ of the quantized probabilistic function (Eq. 29) for a complete variation of probability *p*.

(a)   (b)

(a) graphs of the results of the degrees of favorable evidence $\mu_{(p)}$ (Eq 24) and unfavorable evidence $\lambda_{(p)}$ (Eq 25); **(b)** simulation results of the degrees of certainty and contradiction, according to Eqs (26) and (27), respectively, and the unitary module M(ψ)I$_1$ of the quantized probabilistic function (Eq. 29) for a complete variation of probability.

2.2 Results Related to the Ground-State Energy of the Paraconsistent Model of an Atom

Figure 7 shows the simulation results with explications about the utilized equations, and the interlaced PqL bilattice circumscribed in the external orbital circumference.

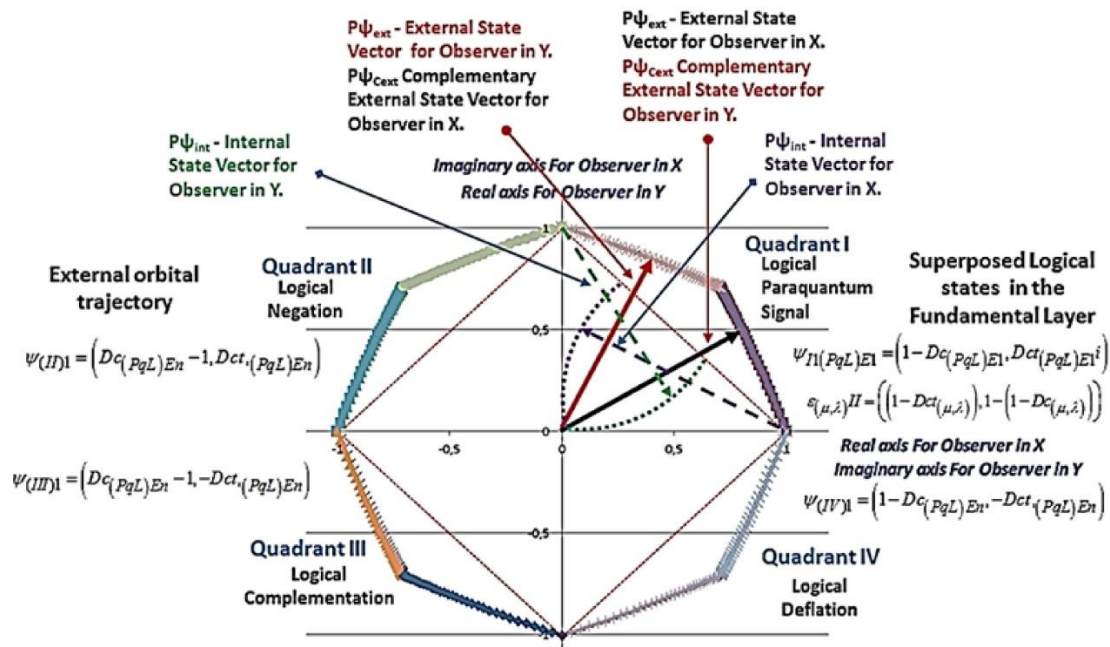

Figure 7. Results related to the fundamental PqL-equations for the energy shell. Simulation of the ground-state energy of the atom using the equations of Quadrant I and the PqL operators and results with explications about the utilized equations and the interlaced PqL bilattice circumscribed in the external orbital circumference.

In this simulation, we used Eqs (24) to (27) and the logical operations of negation, complementation, and conflation.

Figure 8 shows the results simulated with a group of Shannon entropy functions, which are obtained using the equations of the degrees of certainty in six atomic shells of the paraconsistent model of the atom for nondegenerate states.

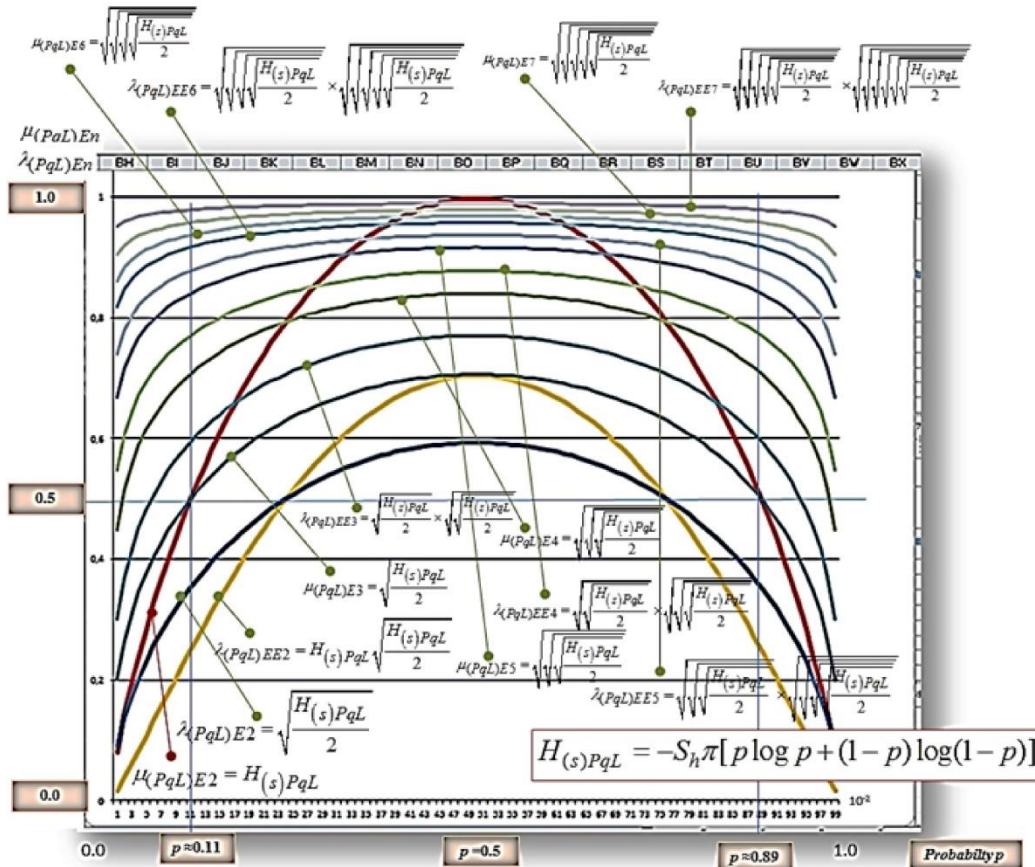

Figure 8. Graphs resulting from the energy shell with fundamental PqL-equations from the *X* observer. Simulation results obtained using a group of Shannon entropy functions for calculating the certainty degree equations in six atomic shells of the paraconsistent model of the atom for the pure or nondegenerate states.

Figure 9 (a) shows the simulation results with explications about the utilized equations and the interlaced PqL bilattice circumscribed in the orbital circumference and energy levels.
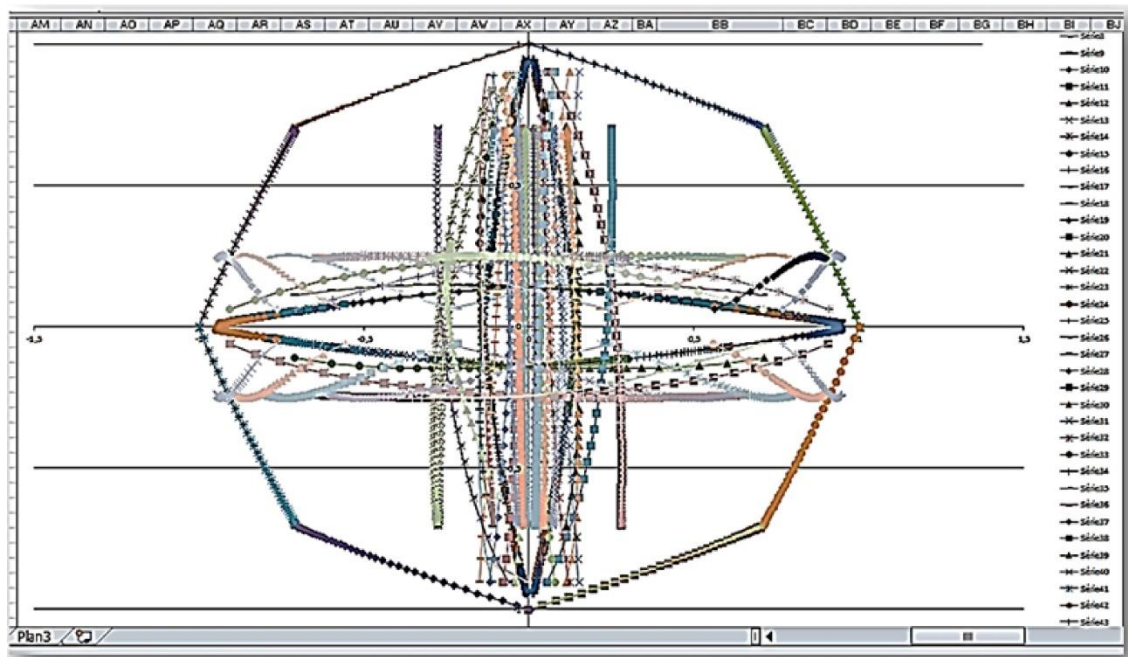

Figure 9(b) shows the paraconsistent model of the complete atom with the orbital energy paths of the shells represented by the degrees of certainty and contradiction for the two references of the *X* and *Y* observers.

In this simulation, we used Eqs. (24) to (76) and the adapted equations shown in the "PqL Equations for the *Y* Observer" section, with the logical operations of negation, complementation, and conflation.

(a) simulation results of the complete paraconsistent model of the atom with degenerate and nondegenerate states; **(b)** simulation results of the complete paraconsistent model of the atom with all probabilistic trajectories of the particles in the six equated atomic shells.

2.3 Results Related to the Wave Functions in the Paraconsistent Model of the Atom

With the probabilistic variables established by the PqL equations in which Shannon entropy functions are included, the $Dc_{(PqL)E1}$ and $Dct_{(PqL)E1}$ values are transformed into functions representing the probability emanating from the logical model of the atom.
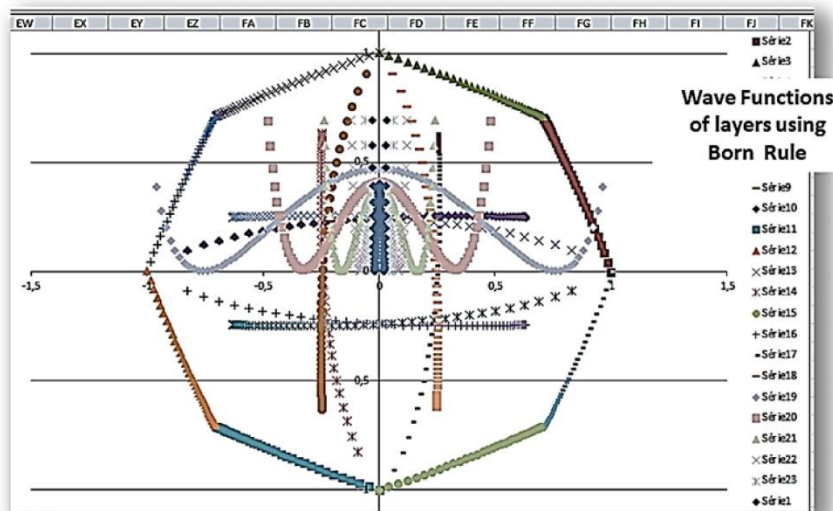

The wave function for each shell of the paraconsistent model of the atom is derived by multiplying the paraquantum logical state with the conjugate complex, according to Eq (2). For the ground-state energy, the wave function $|\psi|^2$ is calculated using $\left|\psi_{\left(\mu_{(PqL)},\lambda_{(PqL)}\right)}\right|^2 = \psi_{(PqL)E1} \times \psi^*_{(PqL)E1}$ or

$$\left|\psi_{\left(\mu_{(PqL)},\lambda_{(PqL)}\right)}\right|^2 = \left[\left(1-Dc_{(PqL)E1}\right)+Dct_{(PqL)E1}i\right] \times \left[\left(1-Dc_{(PqL)E1}\right)-Dct_{(PqL)E1}i\right] \tag{47}$$

where $Dc_{(PqL)E1}$ is presented in Eq. (26), and $Dct_{(PqL)E1}$ is presented in Eq (27). For the other atomic shells, the axes of the references and the amplitudes of the degrees of certainty and contradiction derived by the equations will be considered.

The graphs obtained by the applications of the equations that are related to the wave functions are shown in **Fig. 10**(a).

Figure 10(b) shows the six wave functions represented in the paraconsistent model of the atom with orbital energy paths of shells E_1, E_2, and E_3 for the X and Y observers.

2.4 Results Related to the Heisenberg Uncertainty Principle in the PqL

The reversibility characteristic of the PqL ensures that the degrees of evidence of probability can be obtained through Eqs. (7) and (8).

The certainty degrees at the x-axis $\left(Dc_{(PqL)E}\right)$ and the contradiction degrees at the y-axis $\left(Dct_{(PqL)E}\right)$ in the associated interlaced PqL bilattice can be mapped back to the USCP, where the degrees of evidence $\mu_{(p)}$ and $\lambda_{(p)}$ are plotted in the x- and y-axes. For the typical paraquantum logical state, that is, $\psi_{(PqL)} = \left(Dc_{(PqL)}, Dct_{(PqL)}\right)$, the degree of favorable evidence when the value of the degree of contradiction is 0 can be calculated using $\mu_{(p)} = \frac{1}{2}Dc_{(\mu,\lambda)} + \frac{1}{2}$, which is the normalized value for $Dc_{(PqL)E}$. With this procedure, the normalized value for the contradiction degree is obtained using $\mu_{(p)} = \frac{1}{2}Dct_{(\mu,\lambda)} + \frac{1}{2}$. We can make this normalization for the external paraquantum logical state of the type $\psi_{(PqL)} = \left(1 - Dc_{(PqL)}, Dct_{(PqL)}\right)$, where the normalized value for $1 - Dc_{(PqL)}$ is considered the uncertainty for the x-axis, computed as:

$$\Delta x_{(PqL)} = \frac{\left(1 - Dc_{(PqL)}\right) + 1}{2} , \tag{48}$$

and the normalized value for $Dct_{(PqL)}$ is considered the uncertainty for the y-axis, computed as:

$$\Delta y_{(PqL)} = \frac{Dct_{(PqL)} + 1}{2} . \tag{49}$$

With Eqs (48) and (49), the formal inequality of the Heisenberg uncertainty principle expressed in Eq (1) is represented in the PqL as follows:

$$\Delta x_{(PqL)} \Delta y_{(PqL)} \geq \frac{h}{2} . \tag{50}$$

The graphical results of the simulations with the Heisenberg uncertainty principle equations are shown in **Fig. 11**(a).

2.5 Results Related to the Calculation of the Probability Value in the Paraconsistent Model

The PqL is a reversible logic, and in this manner, we can analyze the paraconsistent model of the atom from its inner part, considering the nucleus as the energy generator that spreads its values to its external part. With the equations considered in this manner, we can estimate the probable values of energy, as well as the probable location of the energy around the generating nucleus. The reversibility characteristic of the PqL ensures that the degrees of evidence of probability can be obtained through Eqs (7) and (8), and the result of its normalized value can be compared with Bernoulli's probabilistic function presented in Eq (14).

This comparison shows that the following equality is a good approximation: $\mu_{(p)} = 2\sigma$, where σ is the standard deviation of probabilistic measures. With $\sigma = \frac{\mu_{(p)}}{2}$ and variance $Var = \sigma^2$, the variance in the PqL can be defined as $Var = \left(\frac{\mu_{(p)}}{2}\right)^2 = \frac{\mu_{(p)}^2}{4}$. The variance related to the degree of unfavorable evidence can be computed using $Var = \lambda_{(p)}^4$. In this case, the variance can be represented by the values of the degrees of certainty and contradiction, such that

$$Var_{(PqL)} = \left(\frac{-Dc_{(PqL)} + Dct_{(PqL)} + 1}{2}\right)^4 . \tag{51}$$

From Eq (12), we can obtain the *p* values by combining the variance equation with a second-degree equation and applying Bhaskara's method, such that
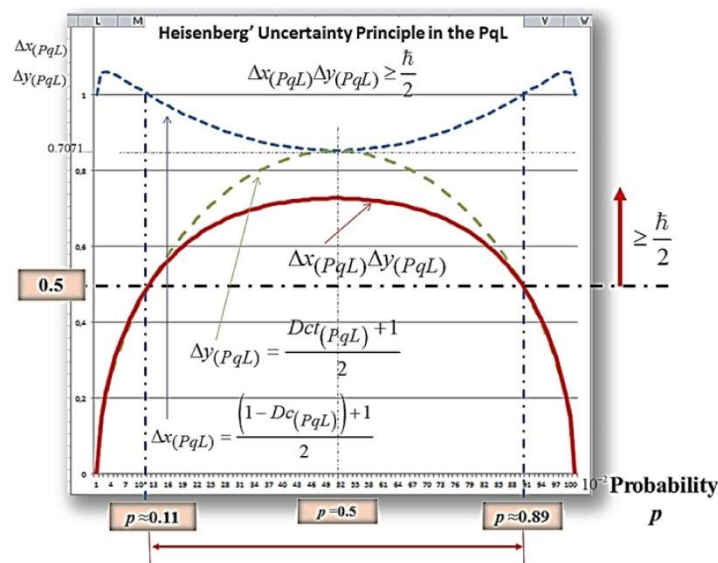

$$p = \frac{1+\sqrt{1-\left[4Var_{(PqL)}\right]}}{2} \, .$$ (52)
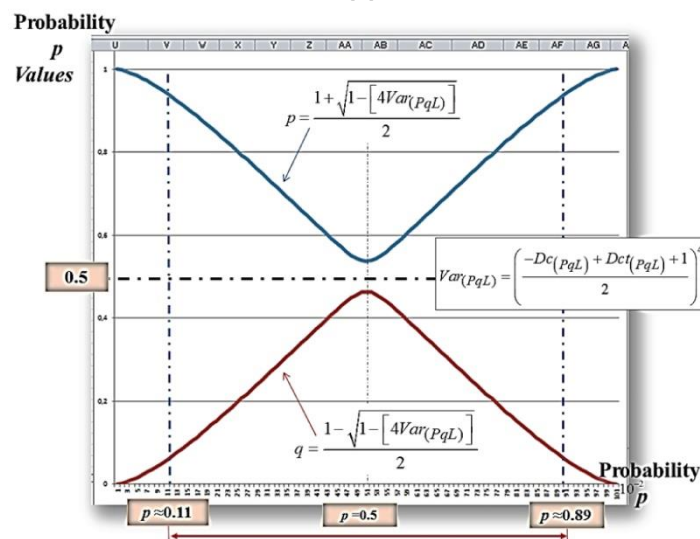

For the complement, $q = 1 - p$ or

$$q = \frac{1-\sqrt{1-\left[4Var_{(PqL)}\right]}}{2} \, .$$ (53)

Figure 11(a) shows the results of the simulation of the Heisenberg uncertainty principle based on Eqs (48), (49), and (50).

Figure 11(b) shows the results of the simulation of Eqs (51) and (52), with probability values ranging from 0 to 1.0 as p and from 1.0 to 0 as the complement q, where $q = 1 - p$.

2.6 Simulation Results with Energy Shell Values for the Hydrogen Atom

In this work, the paraconsistent model of the atom constructed with the probabilistic function of Shannon's entropy will be correlated to the hydrogen atom through the Rydberg formula. In this way, the energy values obtained in the paraconsistent atom model simulation are all correlated with the values defined in Eq (13); therefore, for application in the hydrogen atom, the Rydberg energy is the unit for energy and is calculated by

$E_{Ryd} = \dfrac{m_e e^4}{2(4\pi \in_0)^2 h^2} = R_\infty hc$, where the Rydberg constant is $R_\infty = 10973731.568527 m^{-1}$, h is the Planck's

constant, and c is the speed of light. For this condition the Rydberg energy is $E_{Ryd} = R_\infty hc$, therefore

$E_{Ryd} = 2.179872085 \times 10^{-18} J$.

With $e = 1.60217653 \times 10^{-19} C$, then $E_{Ryd} = 13.60569225 \ eV$.

As previously discussed, the energy values in each atomic shell will be obtained by multiplying each value of the degree of certainty obtained in each atomic shell of the paraconsistent model of the atom by the value of the ground-state energy of the hydrogen atom. For a better visualization of the results in the graphs, we will use in the equations the module of energy value $|E_{Ryd}| = 13.6 \ eV$.

2.6.1 Energy Equations to Stabilize the Graphical Results in the Shells of Hydrogen Atom.

An adjustment factor F_{adj} is considered from the observation of the extreme results $(\geq p_{\max})$ and $(\leq p_{\min})$ obtained using Eq. (34), where the necessity of a multiplicative value to attenuate the value of the extremes by about 85% is verified. Considering that the Shannon normalization factor value is $S_h = 1.057402554$, the

F_{adj} will be the inverse of the cube of the normalization factor, such that $F_{adj} = \dfrac{1}{S_h^3} = 0.845821917$. For the

energy between shells 1 and 2, the corresponding maximum multiplicative value will be

$\dfrac{1}{S_h^3}\left(1 - \dfrac{1}{\sqrt{2}}\right) = 0.247656$. To keep in the shells the energy amplitude at constant values over the range

defined by the maximum $(p_{\max} = 0.89)$ and minimum $(p_{\min} = 0.11)$ values of probability, we will apply the adjustment factor F_{adj} in the equation (34) and the other equations of degrees of certainty that are in **Appendix A**.

From Eq (34), the adjustment factor of $F_{adj} = \dfrac{1}{S_h^3}$ is applied to the degree of certainty to determine the

energy of the second atomic shell with a constant value over the range defined by the maximum ($p_{(max)}$) and minimum ($p_{(min)}$) values of probability. Equation (34) in this adjusted format for a hydrogen atom becomes

$$En_{(PqL)E2} = \left[\dfrac{1}{S_h^3}\left(H_{(s)PqL} - H_{(s)PqL}\sqrt{\dfrac{H_{(s)PqL}}{2}}\right)\right] \times 13.6 \ eV \ . \tag{54}$$

These procedures for PqL equations can be continued for n atomic shells of the paraconsistent model applied to the hydrogen atom.

The PqL equations for the third, fourth, fifth and sixth energy shells of the paraconsistent model of the atom hydrogen are showed in **Appendix B**.

Figure 12(a) shows the simulation results for energy shells in the degenerate states of the hydrogen atom in the paraconsistent model of the atom by application of the application of equation (34) and the other equations of degrees of certainty that are in **Appendix A**.

Figure 12(b) shows the results of the paraconsistent functions of the energies obtained from the hydrogen

atom using multiples of the adjustment factor of $\dfrac{1}{S_h^3}$.

Energy shell values for the hydrogen atom: (a) Energy values of the atomic shells in the paraconsistent model of the atom in the representation based on PqL-Equations. **(b)** Energy values of the atomic shells in the hydrogen atom obtained with PqL-Equations in the application of the adjustment factor.

2.7 Results of the Paraconsistent Model of the Atom Applied to Raman Spectroscopy

Data from Raman spectroscopy are obtained through vibrational processes of molecules involving laser application and capturing responses in the form of energy pulses. The obtained Raman information is related to the spectral lines that are provided as frequency-dominated Raman shifts or wavenumbers expressed in cm^{-1}. In this research, we experimentally investigate how the paraconsistent model of the atom responds to variations in a particular wavelength range. This experimental simulation involves applying the normalized values of Raman intensity in the equation of the degree of favorable evidence presented in Eq (23). In this application, the values of probability p are replaced in the Shannon entropy function by the complement of the normalized values of Raman intensity $(1-I_{Raman})$ throughout the spectrum of the sample.

$$H_{(s)PqL(k)} = -S_h \pi [I_{Raman(ni)} \log I_{Raman(ni)} + (1-I_{Raman(ni)}) \log(1-I_{Raman(ni)})]. \quad \text{As} \quad \mu_{(PqL)k} = H_{(s)PqL(k)},$$

the degree of evidence, which is probabilistic, is modified and becomes the degree of evidence of Raman intensity, with spectroscopy characteristics that interfere with the energy amplitude values in the hydrogen atom shells.

Figure 13(a) shows two Raman spectroscopy signals in the 400 to 1,400 cm^{-1} range, which were recorded from a lubricating mineral oil sample. The first spectrum (Type 1) is related to the Raman data of normal lubricating mineral oil, and the second spectrum (Type 2) shows the Raman data of non-normal lubricating mineral oil. The Type-2 (non-normal) lubricating mineral oil had its temperature controlled and maintained at

approximately 127.5 °C for 8 h and cooled to room temperature to obtain the Raman sample. The two Raman data spectra were applied to the paraconsistent model of the hydrogen atom and analyzed through the representation of the energy levels of the shells presented in this work.

Figure 13(b) shows the simulation results obtained for the energy levels of the six shells in the paraconsistent hydrogen atom. In a superficial analysis, it is verified that the spectrum of the normal lubricating mineral oil (Type 1) presents variations in the shells of the atom at several wavelengths.

Some parts of the spectrum of the non-normal lubricating mineral oil (Type 2) exhibit a few energy variations in the shells of the atom considering the investigated spectrum range.

(a)

(b)

**Figure 13. Practical example results of the paraconsistent model of the atom applied using Raman spectroscopy analysis: (a)** Raman spectroscopy signals from a lubricating mineral oil sample considered normal (Type 1) and non-normal (Type 2; heated for a preset time) (in 1-l$_{Raman}$ normalized values); **(b)** simulation results obtained for the energy levels of the six atomic shells in the paraconsistent hydrogen atom.

2.8 Discussion

The equations presented in this work, as well as the method of obtaining them through interpretations of the interlaced PqL bilattice, follow the fundamentals of PAL2v, where the degree of favorable evidence μ must be accompanied by the degree of unfavorable evidence λ to form the annotation. In the same manner, the degree of certainty Dc must be accompanied by the degree of contradiction Dct to form the paraconsistent logical state.

In **Fig. 6**(a), the graphs of the results obtained by simulations with Shannon entropy show how the variation of probability p creates the path of logical states within the interlaced PqL bilattice. Notably, the correlation value of 0.5 between the curves of the degrees of evidence is the point that defines the boundaries ($p_{(min)}$ = 0.11 and $p_{(max)}$ = 0.89) between the evolution of the states in a balanced quantum system and the collapse of the wave function with the definition of a false or true final logical state.

Figure 6(b) shows the unit value of the modulus of the internal vector $P\psi_{int}$ that moves to create a geometric arc. The limits of its slope are defined by the equations of the Shannon entropy, and its movement with the two external vectors created by the complementarity of values indicates the uncertainty in the movement directions of these vectors.

The paraconsistent model of the atom presents the uncertainties that lead to incompleteness in the measurements, which is expected of a quantum system. This was demonstrated in the results of the simulations shown in **Figs. 7**(a) and **7**(b), where the movements of the external vectors are antagonistic.

In **Fig. 8**, the results show the models separated by the reference of two observers.

Figure 9 shows the simulation results for the complete paraconsistent model of the atom, as well as its projection of the state vectors in the imaginary y-axis of the contradiction and in the real x-axis in the case of an effected measurement. It was demonstrated how the actions of negation, complementation, and conflation operators applied to the logical states enabled the expansion of the probability values. From the analysis, the results obtained by the application of the operators to the logical states of Quadrant I show that the probabilistic trajectories of the particles in the atomic shells appear simultaneously in two directions, that is, clockwise and counterclockwise.

For a practical interpretation, the external and internal probabilistic trajectories of the paraconsistent model of the atom mean that the PqL operations (negation, complementation, and conflation) occur simultaneously, acting in four quadrants of the interlaced PqL bilattice. For an observer in X, in the first quadrant, each paraquantum logical state located at the end of the external state vector ($P\psi_{ext}$) simultaneously generates a paraquantum logical state located at the end of the complementary external state vector ($P\psi_{Cext}$). This is also the same for a Y observer; thus, four paraquantum logical states are generated in Quadrant I. Therefore, each single logical state of the paraconsistent model of the atom is, in the reality, composed of eight paraquantum logical states. As each paraquantum logical state has one equation for the degree of certainty and one equation for the complement of the degree of contradiction, then 16 equations are used for this representation.

In the construction of the model, each of these PqL equations receives the probabilistic value p and its complement $(1-p)$ so that through the Shannon entropy functions they can present the paraconsistent results. The variations of the probabilistic values and the frequency in which they are applied in the PqL equations result in the trajectories presented in the paraconsistent model of the atom. The countless PqL-equations of the paraquantum logical states obtained in the atom shells simultaneously generate all the internal trajectories that are presented in the paraconsistent model.

In the paraconsistent model of the atom, the internal state vector with a unitary module ($P\psi_{int}$) has its variation only within the interlaced PqL bilattice. In this way, this internal vector, $P\psi_{int}$, supports all formalization of PqL through the paraquantum logical states located at its end. The external state vector ($P\psi_{ext}$), in turn, exceeds the limits of the interlaced bilattice and represents energy values through its paraquantum logical states located at its end. In this way, the actions of these two vectors show through the probabilistic trajectories of the particles in the paraconsistent model of the atom a clear interface between the logical universe and the real/quantum world.

Figures 10(a) and **10**(b) show the simulation results of the wave functions for the ground-state energy shell and the wave functions for the other internal energy shells. These results verify the limits that define the evolution of the states.

Figure 11(a) illustrates the validation of the results of the simulation with the Heisenberg uncertainty principle in the PqL, and **Fig. 11**(b) shows that it is possible to obtain the value of the probability p considering only the values of the degrees of certainty and contradiction.

With these simulations, quantum concepts, such as probability density and wave function, are well-established by the equations and probabilistic functions in the PqL. It is highlighted here that in the simulations performed to obtain the wave functions, the Heisenberg uncertainty principle equations, the probability values, and the values of the degrees of certainty and contradiction that make up the paraquantum logical states were used as input. The results demonstrate the application of the reversibility characteristic in the paraconsistent model of the atom.

In **Fig. 12**, the energies of the orbital shells represented by the pairs of values are well delineated in the representation of the hydrogen atom, with values close to those obtained by the Bohr model. On the basis of the results presented in **Fig. 12**, the experiments with Raman spectroscopy have been elaborated, which results are presented in **Fig. 13**. A visual analysis of the results shown in **Fig. 13**(b) indicates that with PqL equations, the differences in energy variations between a normal lubricating mineral oil (Type 1) and a non-normal lubricating mineral oil (heated at 127.5 °C for 8 h; Type 2) can be verified. Therefore, this PqL-based technique can be useful for spectroscopic signal analysis and the verification of material properties at atomic levels.

In general, the simulation results define the probabilistic characteristics of the particle, whereby in quantum mechanics, before the measurement, any of the physical properties are always indefinite. In this manner, the configuration model exhibits the geometry of a sphere and can be described using equations that consider angular variables. A representation of the two planes can be made according to **Fig. 9**, where the orthogonality of the two planes forms an octahedron in which an analysis of the external and internal variables in the equations validates the variation of probability. With the probability representation obtained through the PqL equations in which the Shannon entropy is introduced, we can derive the equations of the degrees of certainty and contradiction by applying the conditions used for a paraconsistent Bloch sphere as an example.

3. Conclusions

The paraconsistent model of the atom proposed in this work is based on the foundations of the PAL and combines the concepts of the entropy of information theory with quantum mechanics. The proposed paraconsistent model of the atom, which applies the interlaced PqL bilattice, shows a convincing geometric aspect for the atomic particle. Thus, well-adjusted fundamentals for the phenomena of quantum physics have been demonstrated. Despite the impossibility of covering all quantum phenomena in this work, the equations obtained by the analyses provide the characteristics of symmetry, recurrence, and superposition of states. The quantum phenomenon of the superposition of states is explicitly expressed through the equations and the representation in which two observers are active. This procedure, which was conducted through the simultaneous use of equations and the analysis of an observer in the vector of the base X and an observer in the vector of the base Y, is similar to the quantum theory. The model presented in this work is innovative and opens a field of in-depth investigations of different conditions and the effects originating from interpretations of the model under diverse conditions and dimensions. All the equations feature good computability and ensure that all the procedures can be presented in matrix forms. Notably, in the presented paraconsistent model of the atom, no equation results in a defined value. In general, all the equations used in the simulations are probabilistic functions that result in indefinite trajectories of paraquantum logical states. Even the direction and orientation of the orbital trajectories shown in the result graphics are indefinite because they are always opposite to one another. In the simulations, the paraconsistent model of the atom was represented by equations that allowed showing the probabilistic trajectories of the paraquantum logical states that can be related to the probable orbits of the elementary particles. With the simulations carried out applying the PqL-equations, the energy functions, represented by the degrees of certainty and contradiction, therefore, values

generated in the quantum universe - Interlaced PqL Bilattice -, can express the probabilities to be measured in the real world. These equations have high significance for the beginning of new studies in computational applications of PqL. In its application to Raman spectroscopy data, the paraconsistent model showed versatility and a good representation of the energy variations at the atomic level of hydrogen. This work demonstrates that the use of the Shannon entropy in a paraconsistent model is an excellent method for modeling quantum systems. In the future, new simulation procedures will expand the application possibilities of the paraconsistent model of the atom in other areas, including computation, quantum logic gates, quantum systems for signal recognition, and quantum cryptography.

Appendix A

A1. Equations for Third atomic shell of Energy

The degree of favorable evidence μ is equal to the degree of unfavorable evidence previously presented in Eq (25). Therefore, $\mu_{(PqL)E3} = \sqrt{\dfrac{H_{(s)PqL}}{2}}$.

The intermediary degree of unfavorable evidence will be obtained through the square root of $\mu_{(PqL)E3}$, therefore $\lambda_{(PqL)E3} = \sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}$.

The degree of unfavorable evidence of the third atomic shell will be obtained by multiplication with the degree of favorable evidence, such that $\lambda_{(PqL)EE3} = \sqrt{\dfrac{H_{(s)PqL}}{2}} \times \sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}$.

With these values of the degrees of evidence, the degree of certainty for the energy level E_3 will have a constant value over a reasonable range of probability variation p. Therefore, the degree of certainty for the third atomic shell of energy will be computed using

$$Dc_{(PqL)E3} = \sqrt{\frac{H_{(s)PqL}}{2}} - \left(\sqrt{\frac{H_{(s)PqL}}{2}} \times \sqrt{\sqrt{\frac{H_{(s)PqL}}{2}}} \right) .$$ Moreover, the degree of contradiction for the energy level E_3 can be derived as follows:

$$Dct_{(PqL)E3} = \sqrt{\frac{H_{(s)PqL}}{2}} + \left(\sqrt{\frac{H_{(s)PqL}}{2}} \times \sqrt{\sqrt{\frac{H_{(s)PqL}}{2}}} \right) - 1 .$$

In the third atomic shell, the degenerate paraquantum logical state will be represented by the function:

$\left| \psi \right\rangle_{(PqL)E3\deg} = \left(1 - Dc_{(PqL)E3} \right) \left| 0 \right\rangle + Dct_{(PqL)E3} \left| 1 \right\rangle$. The nondegenerate paraquantum logical state will be represented by the functions expressed as follows:

$\psi_{(PqL)E3non\deg} = \left(1 - Dc_{(PqL)E3}, Dct_{(PqL)E1} \right)$.

A2. Equations for Fourth atomic Shell of Energy

The degree of favorable evidence is equal to the degree of unfavorable evidence previously derived.

Therefore, $\mu_{(PqL)E4} = \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}$.

The degree of unfavorable evidence will be obtained through the square root of $\mu_{(PqL)E4}$. Therefore,

$$\lambda_{(PqL)E4} = \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} \ .$$

The degree of unfavorable evidence of the energy level (E_4) of the current state is calculated by

multiplication, such that $\lambda_{(PqL)EE4} = \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}}$. The degree of certainty for energy level

E_4 can be derived as follows:

$$Dc_{(PqL)E4} = \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}} - \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} \ .$$

The degree of contradiction for energy level E_4 can be derived as follows:

$$Dct_{(PqL)E4} = \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}} + \sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} - 1 .$$

The degenerate paraquantum logical state will be represented by the function:

$$|\psi\rangle_{(PqL)E4\deg} = \left(\left(1 - Dc_{nd(PqL)E4} \right) \right) |0\rangle + \left(Dct_{nd(PqL)E4} \right) |1\rangle .$$

The nondegenerate paraquantum logical state will be represented by the functions expressed as follows:

$$\psi_{(PqL)E4non\deg} = \left(1 - Dc_{(PqL)E4}, Dct_{(PqL)E1} \right) .$$

A3. Equations Fifth atomic Shell of Energy

The degree of favorable evidence is equal to the degree of unfavorable evidence previously derived.

Therefore, $\mu_{(PqL)E5} = \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}}$.

The degree of unfavorable evidence will be obtained through the square root of $\mu_{(PqL)E5}$, therefore

$$\lambda_{(PqL)E5} = \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}}} \ .$$

The degree of unfavorable evidence of the energy level (E_5) of the current state is calculated by

multiplication, such that $\lambda_{(PqL)EE5} = \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}}}$. In this case, the degree of certainty for

energy level E_5 can be derived as follows: $Dc_{(PqL)E5} = \sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} - \left(\sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\dfrac{H_{(s)PqL}}{2}}}}}} \right) .$

The degree of contradiction for energy level E_5 can be derived as follows:

$$Dct_{(PqL)E5} = \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} + \left(\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \right) - 1 \; .$$

In the fifth atomic shell, the degenerate paraquantum logical state will be represented by the function:
$|\psi\rangle_{(PqL)E5\deg} = \left(\left(1 - Dc_{nd(PqL)E5}\right) \right) |0\rangle + \left(Dct_{nd(PqL)E5} \right) |1\rangle$. The nondegenerate paraquantum logical state will be

represented by the functions expressed as follows: $\psi_{(PqL)E5non\deg} = \left(1 - Dc_{(PqL)E5}, Dct_{(PqL)E1}\right)$.

A4. Equations for Sixth Atomic Shell of Energy

In the sixth atomic shell, the degree of favorable evidence is equal to the degree of unfavorable evidence

previously derived. Therefore, $\mu_{(PqL)E6} = \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}}$.

The degree of unfavorable evidence will be obtained through the square root of $\mu_{(PqL)E6}$. Therefore,

$$\lambda_{(PqL)E6} = \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}}} \; .$$

The degree of unfavorable evidence of the energy level (E_6) of the current state is calculated by

multiplication, such that $\lambda_{(PqL)EE6} = \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}}}$. The degree of certainty for energy

level E_6 can be derived as follows:

$$Dc_{(PqL)E6} = \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} - \left(\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \right) .$$ The degree of contradiction for energy level E_6 can

be derived as follows: $Dct_{(PqL)E6} = \sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} + \left(\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}} \times \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{\frac{\overline{\overline{H_{(s)PqL}}}}{2}}}}}} \right) - 1$.

In the sixth atomic shell, the degenerate paraquantum logical state will be represented by the function:
$|\psi\rangle_{(PqL)E6\deg} = \left(\left(1 - Dc_{(PqL)E6}\right) \right) |0\rangle + \left(Dct_{(PqL)E6} \right) |1\rangle$. The nondegenerate paraquantum logical state will be

represented by the functions expressed as follows: $\psi_{(PqL)E6non\deg} = \left(1 - Dc_{(PqL)E6}, Dct_{(PqL)E1}\right)$.

Appendix B

B1. Equation for Third Energy Shell of hydrogen atom

From PqL-Equations of Appendix A the energy values of atomic shell 3 can be computed using multiples of

the adjustment factor of $\dfrac{1}{S_h^3}$. For Third Energy shell in this adjusted format for a hydrogen atom the pQL-

Equation becomes:

$$En_{(PqL)E3} = \frac{1}{S_h^5} \left[\frac{1}{S_h^6} \sqrt{\frac{H_{(s)PqL}}{2}} - \left(\frac{1}{S_h^6} \sqrt{\frac{H_{(s)PqL}}{2}} \times \sqrt{\frac{1}{S_h^6} \sqrt{\frac{H_{(s)PqL}}{2}}} \right) \right] \times 13.6 \; eV$$

B2. Equation for fourth Energy Shell of hydrogen atom

From PqL-Equations of Appendix A the energy values of atomic shell 4 can be computed using multiples of the adjustment factor of $\frac{1}{S_h{}^3}$. For fourth Energy shell in this adjusted format for a hydrogen atom the PqL-Equation becomes:

$$En_{(PqL)E4} = \frac{1}{S_h{}^{16}} \left[\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}} - \left(\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}} \times \sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}} \right) \right] \times 13.6\ eV$$

B3. Equation for fifth Energy Shell of hydrogen atom

From PqL-Equations of Appendix A the energy values of atomic shell 5 can be computed using multiples of the adjustment factor of $\frac{1}{S_h{}^3}$. For fifth Energy shell in this adjusted format for a hydrogen atom the pQL-Equation becomes:

$$En_{(PqL)E5} = \frac{1}{S_h{}^{25}} \left[\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}} - \left(\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}} \times \sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}}} \times \right) \right] \times 13.6\ eV$$

B4. Equation for sixth Energy Shell of hydrogen atom

From PqL-Equations of Appendix A the energy values of atomic shell 5 can be computed using multiples of the adjustment factor of $\frac{1}{S_h{}^3}$. For sixth Energy shell in this adjusted format for hydrogen atom the PqL-Equation becomes:

$$En_{(PqL)E6} = \frac{1}{S_h{}^{32}} \left[\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}}}} - \left(\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}}}} \times \sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{1}{S_h{}^6}\sqrt{\frac{H_{(s)PqL}}{2}}}}}}} \right) \right] \times 13.6\ eV$$

João Inácio Da Silva Filho has achieved a Bachelor's degree in Electrical Engineering in 1986, with emphasis on Electronics at Santa Cecília University (Unisanta) in the city of Santos, Brazil. In 1996, he obtained a Master's degree in Electrical Engineering – emphasis on the Microelectronics area – and in 1999 completed his Ph.D. in Electrical Engineering with research in Digital Systems by POLI/USP- Polytechnic School of the University of São Paulo in Sao Paulo City, Brazil. In 2009, he did a Post Doctorate at INESC Porto-Institute for systems and Computer Engineering of Porto where he developed studies in the Power Systems Unit (USE) on the campus of the University of Porto in Portugal. He is currently a professor-researcher at Santa Cecília University – Santos City, Sao Paulo, Brazil and is also the Coordinator of the Group of Paraconsistent Logic Applied (GLPA).
